We give a functional limit law for the normalized profile of random plane-oriented recursive trees. The proof uses martingale convergence theorems in discrete and continuous-time. This complements results of Hwang (2007).

Keywords: plane-oriented recursive trees, random trees, profile of trees, preferential attachment, branching random walk, martingales, analysis of algorithms

1 Introduction

We start with a combinatorial definition of plane-oriented recursive trees (PORTs). A PORT is a planar labelled tree with the property that labels along any path down from the root are increasing. Let N_n be the number of these trees of size n with labels $\{1, \dots, n\}$, see Figure 1(a) for an example. Considering the construction node by node, starting with the root labelled by 1, the i -th node has $2i - 3$ possible positions, so we have

$$N_n = (2n - 3)!! = n!2^{1-n}C_n,$$

where C_n denotes the Catalan numbers and $n!! = n \cdot (n - 2) \cdots 3 \cdot 1$ for n odd. A random PORT is obtained by choosing one of these N_n trees uniformly among all. Recently Janson (Jan08) gave an easy coding of PORTs by stirling permutations and obtained results for the distribution of the number of certain types of nodes, in particular leaves.

The above construction suggests a more probabilistic approach, where the PORT is generated by an evolution starting with a single node. In each step we choose the position of the a node uniformly at random. Then, the parent node is chosen with probability proportional to its degree, more precisely the $(i + 1)$ -th node is attached by an edge to an existing node having d children with probability $(d + 1)/(2i - 1)$. This tells us that a random PORT is nothing but a random graph in the so-called preferential attachment model. These graphs have been widely studied recently due to the famous paper by Barabási and Albert (BA99) on network models.

The probabilistic construction of PORTs was first given by Szymański (Szy87). If the parent of a new node is chosen uniformly among all then the resulting tree is known as the random recursive tree (RT). Therefore PORTs are also called *nonuniform* recursive trees, also the term *heap-ordered* trees is used (CN94a),

(CN94b), (CN94c). The preferential attachment rule provides power-law distributions for the number of nodes of the same degree, see (Dur07). Other quantities like typical distances between two nodes or the diameter of the graph are currently under investigation, cf. (vdHHZ07), (vH07).

Properties. We are interested in the profile of random PORTs, i.e. the number of nodes at a given distance to the root. The profile has been investigated for many types of random trees like the binary (or m -ary) search tree (BST) or the recursive tree (RT), see (CDJH01), (CKMR05), (FHN06), (DJN08). It is necessary to distinguish between two types of nodes. Nodes, which are filled with labels are said to be *internal*, whereas possible free nodes where the next label can be placed are called *external*, see Figure 1(b) for an unlabelled PORT with internal and external nodes. We mainly deal with external nodes and denote the number of external nodes in a random PORT of size n on level k by $X_k(n)$, the number of internal by $Y_k(n)$. The processes $(X_k(n))_{k \geq 0}$ and $(Y_k(n))_{k \geq 0}$ are called external and internal profile of the random PORT respectively.

(a) labelled PORT of size $n = 6$

(b) unlabelled port of size $n = 6$ with internal and external nodes

Fig. 1: Example

Obviously we have the following relation

$$Y_{k-1}(n) + Y_k(n) = X_k(n), \quad k \geq 1.$$

Recursively, this leads to

$$Y_k(n) = \sum_{i=1}^k (-1)^{k-i} X_i(n) + (-1)^k.$$

Mahmoud (Mah92) found an expression for the expectation of the external profile

$$\mathbb{E}X_k(n) = 2^{n-k} \frac{s(n, k)}{(2n - 3)!!}, \tag{1}$$

where $s(n, k)$ are the signless stirling numbers of the first kind, i.e. the number of permutations of size n which split in k cycles. Hwang gave asymptotics for the expectation of the internal profile in (Hwa07). Similarly, for any constant $C > 0$, uniformly for $1 \leq k \leq C \log n$, we have

$$\mathbb{E}X_k(n) = \frac{2n^{(z_0+1-z_0 \log z_0)/2}}{\Gamma(z_0/2)\sqrt{z_0 \log n}} \left(1 + O\left(\frac{1}{\log n}\right)\right) \quad (2)$$

with $z_0 = 2k/\log n$. This result is essential for our purpose.

Let H_n be the height of the tree, $H_n = \max\{k \geq 1 : Y_k(n) \geq 1\}$. By (Pit94) (see also (BG97)) it is known that

$$\frac{H_n}{\log n} \xrightarrow{a.s.} c, \quad n \rightarrow \infty,$$

where c is the unique positive solution of $2x - 2x \log(2x) = -1$, $c \approx 1.796$. Note, that this result fits well with (2). In particular if $k \geq (c + \varepsilon) \log n$ for any $\varepsilon > 0$ then $\mathbb{E}X_k(n) = o(1)$. We also see that most external nodes lie at levels $\frac{1}{2} \log n + O(\sqrt{\log n})$, each level having roughly $2n/\sqrt{\pi \log n}$ external nodes. From (Hwa07) it also follows that the degree of the root is about $\sqrt{\pi n}$.

Analysis of the profile. For the asymptotic behaviour of the profile of plane-oriented recursive trees, as in the cases of m -ary search trees or recursive trees, it has turned out that an appropriate scaling is the normalized profile

$$\frac{X_k(n)}{\mathbb{E}X_k(n)}, \quad \text{for } k \sim \alpha \log n.$$

In our case α should be taken from $[0, c]$. For $\alpha = 1/2$ a different scaling is needed to avoid a degenerate limit as in this case we have $\text{Var}X_k(n) = o((\mathbb{E}X_k(n))^2)$. Hwang showed in (Hwa07) that for $k = \frac{1}{2} \log n + s_{n,k}$ with $|s_{n,k}| \rightarrow \infty$ and $s_{n,k} = o(\log n)$ convergence in distribution holds whereas for $s_{n,k} = O(1)$ there is no convergence to a fixed limit due to periodicities.

The following methods have been applied to derive limit results for the normalized profile of various random trees.

- *martingales*: Considering the so-called profil-polynomial, whose coefficients is the profile sequence, leads to a certain family of martingales. Convergence results for these martingales lead to convergence results for the normalized profile by an inversion formula. This method has first been applied in the BST case, see (CDJH01). Katona (Kat05) used similar arguments in the case of trees in the preferential attachment model, in particular PORTs and obtained asymptotic results for the width. Recently this method has been improved by an embedding in a continuous-time model (CKMR05). It gives the strongest results, e.g. functional *a.s.* limit equation in the full domain of interest. However it relies on martingales which only exist in a certain class of random trees.
- *method of moments*: By establishing recursive formulas for the moment series it is possible to show convergence of moments of any order (FHN06), (Hwa07). Typically the limit does not have moments of any order in the whole domain of interest and the approach leads to convergence of the marginal distributions. However, it is the only method so far capable to deal with the central range (here $\alpha = 1/2$).

- *contraction method*: By conditioning on the size of certain subtrees it is possible to derive recursive formulas for internal and external profile. After rescaling it is possible to show that the limit distribution fulfills a certain fixed-point equation. This method works quite well in the cases of BST and RT, however in the plane-oriented recursive tree it has not been applied successfully yet. At the end of the section we will discuss this in greater detail. Note that the contraction method has also been applied to the profil-polynomial in (DJN08).

Results. In (Hwa07), Hwang showed that for $\alpha \in [0, 1/2]$, there exists a random variable $Y(\alpha)$, such that for $k/\log n \rightarrow \alpha$, we have

$$\frac{Y_k(n)}{\mathbb{E}Y_k(n)} \xrightarrow{d} Y(\alpha), \quad n \rightarrow \infty$$

and with convergence of all moments. As mentioned before, for $\alpha > 1/2$ the method of moments fails since the limit, if it exists, does not have moments of any order. This is very similar to BST or RT cases. Our main result is the following functional limit theorem.

Theorem 1 For every compact subset $C \subseteq (0, c)$ there exists a random, non-negative analytic function $M_\infty(z)$, $z \in \mathbb{C}$ with $\mathbb{E}M_\infty(z) = 1$ such that

$$\lim_{n \rightarrow \infty} \sup_{\frac{k}{\log n} \in C} \left| \frac{X_k(n)}{\mathbb{E}X_k(n)} - M_\infty\left(\frac{2k}{\log n}\right) \right| = 0 \quad a.s.$$

Unlike the cases of BST or RT there is no fixed-point equation known for the limit. The following theorem gives some information.

Theorem 2 Let $1 < p \leq 2$ and $z \in \mathbb{R}^+$. Then $\mathbb{E}|M_\infty(z)|^p < \infty$ if and only if

$$-1 + p(z + 1) - z^p > 0.$$

In particular $\mathbb{E}|M_\infty(z)|^p < \infty$ for all $p > 0$ if $z \leq 1$.

Recursive description. We condition on the size $I(n)$ of the first subtree of the root, i.e. the subtree whose root is the second inserted node. This subtree and the remaining tree are again random PORTs, independent of each other. We have

$$Y_k(n) \stackrel{d}{=} Y_{k-1}(I(n)) + Y_k^*(n - I(n)), \quad (3)$$

where $(Y_k^*(n))_{k,n}$ are independent copies of $(Y_k(n))_{k,n}$, both independent of $I(n)$. As mentioned before, the contraction method has been applied to similar recursions for profiles of random trees successfully. Thereby, information is obtained by a fixed-point equation for the limit (after rescaling). However, in our case it is easy to see that

$$I(n) \xrightarrow{d} I, \quad n \rightarrow \infty$$

for some random variable I . So the size $I(n)$ of the first subtree tends to obtain very small values which leads from (3) to a degenerated fixed-point equation. Such cases are typically beyond the scope of the contraction method, an exception being found in (NR04) where asymptotic normality of certain rescaled quantities of logarithmic size is investigated. Another way of decomposing the tree is to consider the

leftmost subtree. Its size is of the same order as the size of the initial tree but unfortunately the remaining tree cannot be treated as a random PORT, basically because the root has too many children.

The paper is organized as follows: In Section 2 a slightly modified version of random PORTs is defined as a Markov chain and an embedding in continuous-time is given. Then our main ingredient, the random profile-polynomial, whose coefficients is the external profile sequence will be considered in both models. We follow the approach of (CKMR05). Based on this polynomial we will find a family of martingales and obtain convergence results for these by well-known properties in the branching random walk. Thereby we always take care for the relation between the discrete and continuous-time models. In Section 3 we will prove Theorem 1 by extracting the profile from the profile-polynomial via a Fourier inversion formula. Also Theorem 2 will be proven here.

2 Continuous-time model and martingales

In the paper we heavily rely on the homogeneous growth rule of the process and therefore modify the model slightly such that the evolution of the process is the same in each step.

We construct a version of the PORT-model as a Markov chain on the space of unlabelled planar trees. At time $n = 0$ start with one external node on level 0. In each step one external node becomes internal and three new external nodes are inserted according to the following rule: Pick one external node, say v uniformly at random among all and make it internal. Then add one external node as a child of v one level beneath, two external nodes as brothers of v at the same level and connect these with the parent of v one level above (if v is at the root level, brothers come without edges). Let T_n be the Markov chain for this process. ∂T_n are the external nodes, $T_n \setminus \partial T_n$ are internal. Obviously

$$|\partial T_n| = 2n + 1, \quad |T_n \setminus \partial T_n| = n.$$

Again, we denote the number of external nodes on level k by $X'_k(n)$. This graph is obtained from the original random PORT by deleting the root with all its edges and shifting levels by one. Since we have $X_{k+1}(n+1) = X'_k(n)$, it suffices to prove Theorem 1 for the modified model. This simplifies calculations and arguments in the following. Observe that (2) implies that for any constant $C > 0$, uniformly for $1 \leq k \leq C \log n$,

$$\mathbb{E}X'_k(n) = \frac{2n^{(z_0+1-z_0 \log z_0)/2}}{z_0 \Gamma(z_0/2) \sqrt{z_0 \log n}} \left(1 + O\left(\frac{1}{\log n}\right) \right) \tag{4}$$

with $z_0 = 2k / \log n$.

We also consider a continuous-time version of this process. At time $t = 0$ start with one living individual at position 0 on the real axis. Each individual lives for an $\text{Exp}(1)$ -distributed lifetime, independent of any other individuals. After its death it gives birth to two children at the same position and one child one step right. Due to the lack of memory, each individual is equally likely to die next. This process is denoted by $(\mathbb{T}_t)_{t \geq 0}$. The set of living individuals at time t is $\partial \mathbb{T}_t$.

Embedding. The counting process N_t gives the number of living individuals at time t

$$N_t = |\partial \mathbb{T}_t|.$$

Let $0 = \tau_0 < \tau_1 < \dots$ be the jump times of the continuous process

$$\tau_n = \inf\{t : N_t = 2n + 1\}.$$

Obviously the jump intervals $(\tau_n - \tau_{n-1})$ are independent and satisfy $\tau_n - \tau_{n-1} \stackrel{d}{=} \text{Exp}(2n - 1)$. In the following we consider positions of individuals as levels, dead individuals as internal nodes and living individuals as external nodes. Furthermore we draw an edge between an individual (or node) and its ancestor one level above (nodes on the root level are not connected). Then, since the jump times are independent of the shape of the tree, we have

$$(\mathbb{T}_{\tau_n})_{n \geq 0} = (T_n)_{n \geq 0}.$$

Let \mathcal{F}_t and $\mathcal{F}(n)$ be the natural filtrations of \mathbb{T}_t and T_n , i.e. $\mathcal{F}_t = \sigma(\mathbb{T}_s : s \leq t)$, $\mathcal{F}(n) = \sigma(T_i : i \leq n)$.

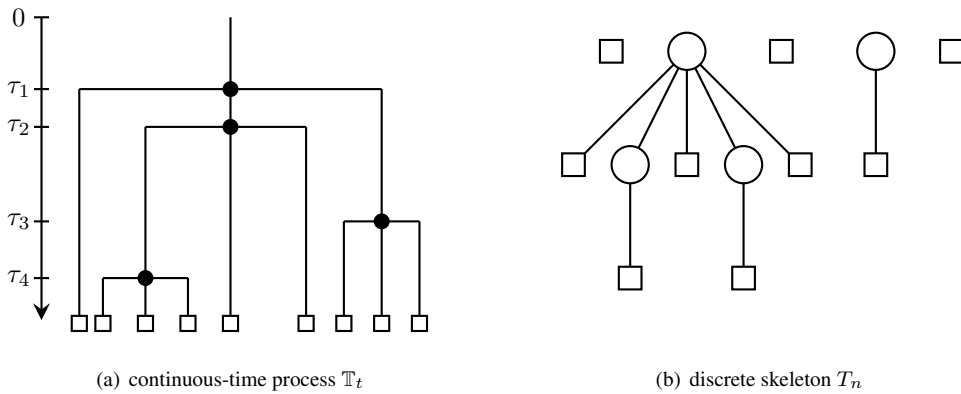

Fig. 2: Embedding

Martingales - discrete case. In the analysis of the profile our main tool will be the so-called profile-polynomial. For $z \in \mathbb{C}$ let

$$W_n(z) = \sum_{k \geq 0} X'_k(n) z^k.$$

Its degree is the external height of the tree. Let D_n be the depth of the n -th inserted node. By construction, we have $X'_k(n + 1) = X'_k(n) + \mathbb{1}\{D_{n+1} \in \{k - 1, k\}\}$. This leads to the crucial observation, that

$$\mathbb{E}[W_{n+1}(z) | \mathcal{F}_n] = \frac{2n + 2 + z}{2n + 1} W_n(z).$$

Let

$$C_n(z) := \prod_{k=0}^{n-1} \frac{2k + 2 + z}{2k + 1}.$$

Then for $z \in \mathbb{C} \setminus 2\mathbb{Z}^-$

$$\left(M_n(z) = \frac{W_n(z)}{C_n(z)} \right)_{n \geq 0} \tag{5}$$

is an $\mathcal{F}(n)$ -martingale with expectation 1. This type of martingale was first observed in the BST case by Jabbour-Hattab, see (JH01).

Lemma 1 We have for $n \geq 1$ and $z \in \mathbb{C} \setminus 2\mathbb{Z}^-$

$$C_n(z) = \frac{2\sqrt{\pi}}{z\Gamma(z/2)} \frac{\Gamma(n+1+z/2)}{\Gamma(n+1/2)} = \frac{2\sqrt{\pi}}{z\Gamma(z/2)} n^{(z+1)/2} \left(1 + O\left(\frac{1}{n}\right)\right)$$

uniformly on every compact subset of $\mathbb{C} \setminus 2\mathbb{Z}^-$.

Proof: The proof is based upon Stirling's formula. For all $z \in \mathbb{C} \setminus \mathbb{Z}^-$ we have

$$\Gamma(z) = \sqrt{2\pi} z^{z-1/2} e^{-z} (1 + \Theta(1/z)),$$

for $|z| \rightarrow \infty$. For convenience we set $\alpha = z/2$. Thus, for n large enough,

$$\begin{aligned} \frac{\Gamma(n+1+\alpha)}{\Gamma(n+1/2)} &= \left(1 + \frac{\alpha+1/2}{n+1/2}\right)^{n+1/2} e^{-(\alpha+1/2)} \frac{(n+1+\alpha)^\alpha}{(n+1/2)^{-1/2}} \left(1 + O\left(\frac{1}{n}\right)\right) \\ &= n^{\alpha+1/2} \left(1 + O\left(\frac{1}{n}\right)\right). \end{aligned}$$

By continuity we can choose the constant in the O -term uniformly on compact sets. □

Remark: It is possible to compute the second order of the profile polynomial explicitly as in (CDJH01). Basically, $M_n(z)$ is bounded in L^2 if $|z-1| < \sqrt{2}$. In this domain the martingale converges in L^2 and following (CDJH01) the a.s. convergence is uniform on compact subsets.

Martingales - continuous case. The measure valued process

$$\varrho_t = \sum_{u \in \partial \mathbb{T}_t} \delta_{|u|}$$

can be seen as a continuous-time branching random walk. Particles do not move and the offspring distribution Z equals $2\delta_0 + \delta_1$. The lifetime parameter β is 1. It is well-known, see (Big92), that

$$m(t, \lambda) = \sum_{u \in \partial \mathbb{T}_t} e^{-\lambda|u|} e^{-\beta t(b(\lambda)-1)}$$

with $b(\lambda) = \mathbb{E} \int e^{-\lambda x} dZ(x)$ is a \mathcal{F}_t -martingale with mean 1 for all $\lambda \in \mathbb{C}$. In our case this gives

$$m(t, \lambda) = \sum_{u \in \partial \mathbb{T}_t} e^{-\lambda|u|} e^{-t(e^{-\lambda}+1)}.$$

Substituting $z = e^{-\lambda}$ we use the martingale

$$\mathcal{M}(t, z) = \sum_{u \in \partial \mathbb{T}_t} z^{|u|} e^{-t(z+1)} = \sum_{k \geq 0} \varrho_t(\{k\}) z^k e^{-t(z+1)}.$$

Observe the analogy with (5), in particular $\varrho_{\tau_n}(\{k\}) = X'_k(n)$. Choosing $z = 1$ we see that $N_t e^{-2t}$ is an \mathcal{F}_t -martingale with mean 1. Since it is non-negative it converges a.s. Let $\xi := \lim_t N_t e^{-2t}$. Since $N_{\tau_n} = 2n + 1$ and $\tau_n \rightarrow \infty$ a.s. we also have

$$\lim_{n \rightarrow \infty} n e^{-2\tau_n} = \xi, \quad (6)$$

in particular

$$\frac{\tau_n}{\log n} \rightarrow \frac{1}{2} \quad a.s.$$

We do not need more precise information about the asymptotics of τ_n .

Martingale connection. Obviously there is an easy connection between the two martingales. Define

$$\mathcal{C}_n(z) := e^{-\tau_n(z+1)} C_n(z).$$

By construction the processes $\mathcal{C}_n(z)$ and $M_n(z)$ are independent and satisfy

$$\mathcal{M}(\tau_n, z) = \mathcal{C}_n(z) M_n(z). \quad (7)$$

Furthermore it is easy to show that $\mathcal{C}_n(z)$ is a $\overline{\mathcal{F}}(n)$ -martingale with mean 1, with $\overline{\mathcal{F}}(n) = \sigma(\tau_1, \dots, \tau_n)$ and by Lemma 1 and (6)

$$\lim_{n \rightarrow \infty} \mathcal{C}_n(z) = \frac{2\sqrt{\pi}}{z\Gamma(z/2)} \xi^{(z+1)/2}, \quad a.s. \quad (8)$$

Convergence of martingales. We turn to the fundamental question in which domain of the complex plane the martingales converge a.s. and in L^1 . The L^1 -convergence is important to ensure that the limit is non-degenerate.

Theorem 3 For $1 < p \leq 2$, let $V_p = \{z : \sup_t \mathbb{E}|M(t, z)|^p < \infty\}$. Then $V_p = \{z : f(z, p) > 0\}$ with

$$f(z, p) := -1 + p(\Re(z) + 1) - |z|^p.$$

If $V = \bigcup_{1 < p \leq 2} V_p$ then $\mathcal{M}(t, z)$ and $M_n(z)$ converge uniformly on compact sets of V , a.s. and in L^1 . We denote the limits by $\mathcal{M}(\infty, z)$ and $M_\infty(z)$.

Proof: The continuous-time result is Theorem 6 in (Big92). For the reduction to the discrete case we proceed as in (CKMR05). By (7) we have

$$\mathcal{C}_N(z)(M_n(z) - M_N(z)) = \mathbb{E}[\mathcal{M}(\tau_n, z) - \mathcal{M}(\tau_N, z) | \overline{\mathcal{F}}(N)]$$

for $n \geq N$. Let $K \subseteq V$ compact and note that $\mathcal{C}_N(z) \geq 0$ for $z \in K$. Taking the absolute value and supremum gives

$$\sup_{z \in K} \mathcal{C}_N(z) |M_n(z) - M_N(z)| \leq \mathbb{E}[\sup_{z \in K} |\mathcal{M}(\tau_n, z) - \mathcal{M}(\tau_N, z)| | \overline{\mathcal{F}}(N)]$$

By $\mathbb{E}\mathcal{C}_N(z) = 1$ and independence of $\mathcal{C}_N(z)$ and $M_n(z)$, taking expectation yields

$$\mathbb{E} \sup_{z \in K} |M_n(z) - M_N(z)| \leq \mathbb{E} \sup_{z \in K} |\mathcal{M}(\tau_n, z) - \mathcal{M}(\tau_N, z)|.$$

Now let $L_N = \sup_{t \geq \tau_N} \sup_{z \in K} |\mathcal{M}(t, z) - \mathcal{M}(\tau_N, z)|$. Then it follows

$$\sup_{n \geq N} \mathbb{E} \sup_{z \in K} |M_n(z) - M_N(z)| \leq \mathbb{E} L_N.$$

The continuous-time result gives $L_N \rightarrow 0$ a.s. By the triangle inequality we can bound L_N by $2L_0 = \sup_{t > 0} \sup_{z \in K} |\mathcal{M}(t, z)|$. By the proof of proposition 3 in (BR) we have $\mathbb{E} L_0 < \infty$. The dominated convergence theorem gives the uniform L^1 convergence of the discrete martingale. The uniform almost sure convergence follows, since $(\sup_{z \in K} |M_n(z) - M_N(z)|)_{n \geq N}$ is a non-negative submartingale. \square

Remark. By computing $\frac{d}{dq} f(z, q)|_{q=1}$ we see that $(0, 2c)$ is included in the domain of convergence and that there is no L^p boundedness for $z \geq 2c$. It is possible to show L^p boundedness of the martingale in the discrete case for real $z \in V_p$ directly by induction using

$$W_{n+1}(z) = W_n(z) + (1 + z)z^{D_{n+1}},$$

where D_n is the depth of the n -th inserted node. This can be strengthened to an open connected subset contained in V_p . If there exists a continuous version of the limit then uniform convergence can be obtained by standard arguments, see (CDJH01) and (JLCN73). For the domain of L^2 convergence this can be done by the holomorphy of the covariance function of the profil-polynomial as in (CDJH01). It is not clear how to extend this to the case $1 < p < 2$.

Due to (7) and (8) we also have the limit martingale connection

$$\mathcal{M}(\infty, z) = \frac{2\sqrt{\pi}}{z\Gamma(z/2)} \xi^{(z+1)/2} M_\infty(z), \quad a.s. \tag{9}$$

By the L^1 convergence of the martingale $\mathcal{M}(t, z)$ we know that $\mathcal{M}(\infty, z) \in L^p$ if and only if $\mathcal{M}(t, z)$ is bounded in L^p . Due to the limit martingale connection (9) and the fact that $\xi \in L^2$ and is independent of $M_\infty(z)$ the same holds in the discrete case. This proves the following corollary.

Corollary 1 For $1 < p \leq 2$, $\mathbb{E}|\mathcal{M}(\infty, z)|^p < \infty$ if and only if $z \in V_p$, where V_p is defined in Theorem 3. The same holds for $M_\infty(z)$.

The following Theorem treats convergence of the martingales in the remaining case.

Theorem 4 For $z \geq 2c$ we have $\lim_t \mathcal{M}(t, z) = \lim_n M_n(z) = 0$ a.s.

Proof: The result in the continuous-time model is again in (Big92). Use the above limit martingale connection to deduce the same result in the discrete case. \square

3 Proof of the main results

It is possible to show a weaker form of Theorem 1 only in the L^2 domain of convergence without embedding as in (CDJH01). For an extension to the general case L^p -bounds for the profil-polynomial are needed not only in a neighbourhood of the real axis but in a larger domain of the complex plane. At the

moment it is not clear how to get these bounds directly. Therefore we proceed as in (CKMR05). First we have to get back the profile from the polynomial by a Fourier inversion formula. By (2) we have

$$\mathcal{M}(t, ze^{ix}) = e^{-t(ze^{ix}+1)} \sum_{k \geq 0} \varrho_t(\{k\}) z^k e^{ikx},$$

for $0 \leq x < 2\pi$. This gives

$$\varrho_t(\{k\}) = \frac{e^{t(z+1)} z^{-k}}{2\pi} \int_{-\pi}^{\pi} \mathcal{M}(t, ze^{ix}) e^{-tz(1-e^{ix})} e^{-ikx} dx.$$

Next we need to substitute the martingale term in the integrand by its limit. This can be done with the following Lemma which is a continuous-time version of Lemma 5 in (Big92). As indicated in (CKMR05) it can be proven by replacing Lemma 6 there with the property that for

$$\beta(t, z) = (\mathcal{M}(t, z) - 1)e^{t(z+1)},$$

it holds

$$\mathbb{E}|\beta(t, z)|^p \leq e^{tp(\Re z+1)} \int_0^t e^{-sf(z,p)} ds, \quad 1 < p \leq 2,$$

where $f(z, p)$ is defined in Theorem 3. This follows from section 2.4 in (Ber03).

Lemma 2 *For any compact subset C of $(0, 2c)$ we have*

$$\sup_{z \in C} \int_{-\pi}^{\pi} \sqrt{t} |\mathcal{M}(t, ze^{i\eta}) - \mathcal{M}(\infty, z)| e^{-tz(1-\cos \eta)} d\eta \xrightarrow{t \rightarrow \infty} 0 \quad a.s.$$

Combining these two results yields

$$2\pi \varrho_t(\{k\}) e^{-t(z+1)} z^k \sqrt{t} = \mathcal{M}(\infty, z) \sqrt{t} \int_{-\pi}^{\pi} e^{-tz(1-\cos x)} e^{-ikx} dx + o(1),$$

the o -term being uniform in $z \in C$. Cauchy's integral formula gives

$$\int_{-\pi}^{\pi} e^{-tz(1-\cos x)} e^{-ikx} dx = 2\pi e^{-zt} \frac{(zt)^k}{k!}.$$

Take $z = 2k/\log n$. A reformulation gives

$$\varrho_t(\{k\}) = z^{-k} e^{t(z+1)} (\mathcal{M}(\infty, z) \Pi(tz)(\{k\}) + o(1)),$$

where $\Pi(\lambda)$ is the Poisson-distribution with parameter λ . Using a local limit theorem for the Poisson-distribution, see (Pet75)

$$\lim_{\lambda \rightarrow \infty} \sup_k \left| \sqrt{2\pi\lambda} P^{(\lambda)}(\{k\}) - e^{-\frac{(k-\lambda)^2}{2\lambda}} \right| = 0,$$

gives

$$\varrho_t(\{k\}) = A_t(k, z) \left(\mathcal{M}(\infty, z) e^{-\frac{(k-tz)^2}{2tz}} + \mathcal{M}(\infty, z) o(1) \right),$$

with

$$A_t(k, z) = \frac{e^{t(z+1)}}{z^k \sqrt{2\pi tz}},$$

and the o -term being uniform in $z \in C$. Remember $\varrho_{\tau_n}(\{k\}) = X'_k(n)$ so we use the stopping times τ_n to return to the discrete profile. Due to (6) we have $\log n - 2\tau_n \rightarrow \log \xi$ and therefore

$$e^{-\frac{(k-tz)^2}{2tz}} = e^{-z \frac{(\log n/2 - \tau_n)^2}{2\tau_n}} = 1 + o(1), \quad a.s.$$

By continuity of $\mathcal{M}(\infty, z)$ it follows

$$X'_k(n) = A_{\tau_n}(k, z)(\mathcal{M}(\infty, z) + o(1)).$$

The result follows by the asymptotics of the expectation of $X_k(n)$ in (4), the limit martingale connection (9) and (6). This proves Theorem 1.

Theorem 2 follows from corollary 1.

Acknowledgements: I thank my advisor Ralph Neininger for his support.
